The minimal deterministic finite automaton is generally used to determine regular languages equality. Antimirov and Mosses proposed a rewrite system for deciding regular expressions equivalence of which Almeida *et al.* presented an improved variant. Hopcroft and Karp proposed an almost linear algorithm for testing the equivalence of two deterministic finite automata that avoids minimisation. In this paper we improve the best-case running time, present an extension of this algorithm to non-deterministic finite automaton, and establish a relationship between this algorithm and the one proposed in Almeida *et al.* We also present some experimental comparative results. All these algorithms are closely related with the recent coalgebraic approach to automata proposed by Rutten.

1   Introduction

The uniqueness of the minimal deterministic finite automaton for each regular language is in general used for determining regular languages equality. Whether the languages are represented by deterministic finite automata (DFA), non deterministic finite automata (NFA), or regular expressions (r. e.), the usual procedure uses the equivalent minimal DFA to decide equivalence. The best known algorithm, in terms of worst-case analysis, for DFA minimisation is loglinear [9], and the equivalence problem is PSPACE-complete for both NFA and r. e. Based on the algebraic properties of regular expressions, Antimirov and Mosses proposed a terminating and complete rewrite system for deciding their equivalence [6]. In a paper about testing the equivalence of regular expressions, Almeida *et al.* [3] presented an improved variant of this rewrite system. As suggested by Antimirov and Mosses, and corroborated by further experimental results, a better average-case performance may be obtained.

Hopcroft and Karp [10] presented, in 1971, an almost linear algorithm for testing the equivalence of two DFAs that avoids their minimisation. Considering the merge of the two DFAs as a single one, the algorithm computes the finest right-invariant relation which identifies the initial states. The state equivalence relation that determines the minimal DFA is the coarsest relation in that condition.

We present some variants of Hopcroft and Karp's algorithm (**HK**) (Section 3), and establish a relationship with the one proposed in Almeida *et al.* (Section 4). In particular, we extend **HK** algorithm to NFAs and present some experimental comparative results (Section 5).

All these algorithms are also closely related with the recent coalgebraic approach to automata developed by Rutten [15], where the notion of *bisimulation* corresponds to a right-invariance. Two automata are bisimilar if there exists a bisimulation between them. For deterministic (finite) automata, the *coinduction proof principle* is effective for equivalence, i. e., two automata are bisimilar if and only if they are equivalent. Both Hopcroft and Karp algorithm and Antimirov and Mosses method can be seen as

---

instances of this more general approach (cf. Corollary 10). This means that these methods may be easily extended to other Kleene Algebras, namely the ones that model program properties, and that have been successfully applied in formal program verification [12].

2   Preliminaries

We recall here the basic definitions needed throughout the paper. For further details we refer the reader to the works of Hopcroft *et al.* [11] and Kozen [13].

A *regular expression* (r. e.) α over an alphabet Σ represents a (regular) language $L(\alpha) \subseteq \Sigma^*$ and is inductively defined by: $\emptyset$ is a r. e. and $L(\emptyset) = \emptyset$; ϵ is a r. e. and $L(\epsilon) = \{\epsilon\}$; $a \in \Sigma$ is a r. e. and $L(a) = \{a\}$; if α and β are r. e., $(\alpha_1 + \alpha_2)$, $(\alpha_1 \alpha_2)$ and $(\alpha_1)^*$ are r. e., respectively with $L((\alpha_1 + \alpha_2)) = L(\alpha_1) \cup L(\alpha_2)$, $L((\alpha_1 \alpha_2)) = L(\alpha_1)L(\alpha_2)$ and $L((\alpha_1)^*) = L(\alpha_1)^*$. We define $\varepsilon(\alpha) = 1$ (resp. $\varepsilon(\alpha) = 0$) if $\epsilon \in L(\alpha)$ (resp. $\epsilon \notin L(\alpha)$). Two r. e. α and β are *equivalent*, and we write $\alpha \sim \beta$, if $L(\alpha) = L(\beta)$. The algebraic structure $(RE, +, \cdot, \emptyset, \epsilon)$, where RE denotes the set of r. e. over Σ, constitutes an idempotent semiring, and, with the unary operator $*$, a *Kleene algebra*. There are several well-known complete axiomatizations of Kleene algebras. Let ACI denote the associativity, commutativity and idempotence of $+$.

A *nondeterministic finite automaton* (NFA) A is a tuple $(Q, \Sigma, \delta, I, F)$ where Q is a finite set of states, Σ is the alphabet, $\delta \subseteq Q \times \Sigma \times Q$ the transition relation, $I \subseteq Q$ the set of initial states, and $F \subseteq Q$ the set of final states. An NFA is *deterministic* (DFA) if for each pair $(q, a) \in Q \times \Sigma$ there exists at most one q' such that $(q, a, q') \in \delta$. The size of a NFA is $|Q|$. For $s \in Q$ and $a \in \Sigma$, we denote by $\delta(q, a) = \{p \mid (q, a, p) \in \delta\}$, and we can extend this notation to $x \in \Sigma^*$, and to $R \subseteq Q$. For a DFA, we consider $\delta : Q \times \Sigma^* \to Q$. The *language* accepted by A is $L(A) = \{x \in \Sigma^* \mid \delta(I, x) \cap F \neq \emptyset\}$. Two NFAs A and B are *equivalent*, denoted by $A \sim B$ if they accept the same language. Given an NFA $A = (Q_N, \Sigma, \delta_N, I, F_N)$, we can use the *powerset construction* to obtain a DFA $D = (Q_D, \Sigma, \delta_D, q_0, F_D)$ equivalent to A, where $Q_D = 2^{Q_N}$, $q_0 = I$, for all $R \in Q_D$, $R \in F_D$ if and only $R \cap F_N \neq \emptyset$, and for all $a \in \Sigma$, $\delta_D(R, a) = \bigcup_{q \in R} \delta_N(q, a)$. This construction can be optimised by omitting states $R \in Q_D$ that are unreachable from the initial state.

Given a finite automaton $(Q, \Sigma, \delta, q_0, F)$, let $\varepsilon(q) = 1$ if $q \in F$ and $\varepsilon(q) = 0$ otherwise. We call a set of states $R \subseteq Q$ *homogeneous* if for every $p, q \in R$, $\varepsilon(p) = \varepsilon(q)$. A DFA is *minimal* if there is no equivalent DFA with fewer states. Two states $q_1, q_2 \in Q$ are said to be *equivalent*, denoted $q_1 \sim q_2$, if for every $w \in \Sigma^*$, $\varepsilon(\delta(q_1, w)) = \varepsilon(\delta(q_2, w))$. Minimal DFAs are unique up to isomorphism. Given a DFA D, the equivalent minimal DFA $D/_\sim$ is called the *quotient automaton* of D by the equivalence relation $\sim$. The state equivalence relation $\sim$, is a special case of a right-invariant equivalence relation w. r. t. D, i. e., a relation $\equiv \subseteq Q \times Q$ such that all classes of $\equiv$ are homogeneous, and for any $p, q \in Q$, $a \in \Sigma$ if $p \equiv q$, then $\delta(p, a)/_\equiv = \delta(q, a)/_\equiv$, where for any set S, $S/_\equiv = \{[s] \mid s \in S\}$. Finally, we recall that every equivalence relation $\equiv$ over a set S is efficiently represented by the partition of S given by $S/_\equiv$. Given two equivalence relations over a set S, $\equiv_R$ and $\equiv_T$, we say that $\equiv_R$ is *finer* then $\equiv_T$ (and $\equiv_T$ *coarser* then $\equiv_R$) if and only if $\equiv_R \subseteq \equiv_T$.

3   Testing finite automata equivalence

The classical approach to the comparison of DFAs relies on the construction of the minimal equivalent DFA. The best known algorithm for this procedure runs in $O(kn \log n)$ time [9], for a DFA with n states over an alphabet of k symbols. Hopcroft and Karp [10] proposed an algorithm for testing the equivalence of two DFAs that makes use of an almost $O(n)$ set merging method.

3.1 The original Hopcroft and Karp algorithm

Let $A = (Q_1, \Sigma, p_0, \delta_1, F_1)$ and $B = (Q_2, \Sigma, q_0, \delta_2, F_2)$ be two DFAs, with $|Q_1| = n$, $|Q_2| = m$, and such that Q_1 and Q_2 are disjoint. In order to simplify notation, we assume $Q = Q_1 \cup Q_2$, $F = F_1 \cup F_2$, and $\delta(p, a) = \delta_i(p, a)$ for $p \in Q_i$. We begin by presenting the original algorithm by Hopcroft and Karp [1] for testing the equivalence of two DFAs as Algorithm 1.

If A and B are equivalent DFAs, the algorithm computes the finest right-invariant equivalence relation over Q that identifies the initial states, p_0 and q_0. The associated set partition is built using the UNION-FIND method. This algorithm assumes disjoint sets and defines the three functions which follow.

- MAKE(i): creates a new set (singleton) for one element i (the identifier);

- FIND(i): returns the identifier S_i of the set which contains i;

- UNION(i, j, k): combines the sets identified by i and j in a new set $S_k = S_i \cup S_j$; S_i and S_j are destroyed.

It is clear that, disregarding the set operations, the worst-case time of the algorithm is $O(k(n + m))$, where $k = |\Sigma|$. An arbitrary sequence of i MAKE, UNION, and FIND operations, j of which are MAKE operations in order to create the required sets, can be performed in worst-case time $O(i\alpha(j))$, where $\alpha(j)$ is related to a functional inverse of the Ackermann function, and, as such, grows *very* slowly. In fact, for every *practical* values of j (up to $2^{2^{2^{16}}}$), $\alpha(j) \leq 4$.

```
1    def HK(A, B):
2        for q ∈ Q:  MAKE(q)
3        S = ∅
4        UNION(p_0, q_0, q_0);  PUSH(S, (p_0, q_0))
5        while (p, q) = POP(S):
6            for a ∈ Σ:
7                p' = FIND(δ(p, a))
8                q' = FIND(δ(q, a))
9                if p' ≠ q':
10                   UNION(p', q', q')
11                   PUSH(S, (p', q'))
12       if ∀S_i∀p, q ∈ S_i   ε(p) = ε(q):  return True
13       else:  return False
```

Algorithm 1: The original **HK** algorithm.

When applied to Algorithm 1, this set union algorithm allows for a worst-case time complexity of $O(k(n + m) + 3i\alpha(j)) = O(k(n + m) + 3(n + m)\alpha(n + m))$. Considering $\alpha(n + m)$ constant, the asymptotic running-time of the algorithm is $O(k(n + m))$. The correctness of this algorithm is proved in Section 4, Theorem 8.

3.2 Improved best-case running time

By altering the FIND function in order to create the set being looked for if it does not exist, i. e., whenever FIND(i) fails, MAKE(i) is called and the set $S_i = \{i\}$ is created, we may add a *refutation* procedure earlier in the algorithm. This allows the algorithm to return as soon as it finds a pair of states such that one is final and the other is not. This alteration to the FIND procedure avoids the initialization of $m + n$

sets which may never actually be used. These modifications to Algorithm 1 are presented in Algorithm 2.

Although it does not change the worst-case complexity, the best-case analysis is considerably better, as it goes from $\Omega(k(n+m))$ to $\Omega(1)$. Not only it is possible to distinguish the automata by the first pair of states, but it is also possible to avoid the linear check in the lines 12–13. The observed asymptotic behaviour of minimality of initially connected DFAs (ICDFAs) [2], suggests that, when dealing with random DFAs, the probability of having two equivalent automata is very low, and a refutation method will be very useful (see Section 5).

Lemma 1. *In line 5 of Algorithm 1, all the sets S_i are homogeneous if and only if all the pairs of states (p,q) pushed into the stack are such that $\varepsilon(p) = \varepsilon(q)$.*

Proof: Let us proceed by induction on the number l of times line 5 is executed. If $l = 1$, it is trivial. Suppose that lemma is true for the lth time the algorithm executes line 5. If for all $a \in \Sigma$, the condition in line 9 is false, for the $(l+1)^{th}$ time the homogeneous character of the sets remains unaltered. Otherwise, it is clear that in lines 10–11, $S_{p'} \cup S_{q'}$ is homogeneous if and only if $\varepsilon(p') = \varepsilon(q')$. Thus the lemma is true. $\square$

```
 1   def HKi(A,B):
 2       MAKE(p_0);  MAKE(q_0)
 3       S = ∅
 4       UNION(p_0,q_0,q_0);  PUSH(S,(p_0,q_0))
 5       while (p,q) = POP(S):
 6           if ε(p) ≠ ε(q): return False
 7           for a ∈ Σ:
 8               p' = FIND(δ(p,a))
 9               q' = FIND(δ(q,a))
10               if p' ≠ q':
11                   UNION(p',q',q')
12                   PUSH(S,(p',q'))
13       return True
```

Algorithm 2: **HK** algorithm with an early refutation step (**HKi**).

Theorem 2. *Algorithms 1 (**HK**) and 2 (**HKi**) are equivalent.*

Proof: By Lemma 1, if there is a pair of states (p,q) pushed into the stack such that $\varepsilon(p) \neq \varepsilon(q)$, then the algorithm can terminate and return *False*. That is exactly what Algorithm 2 does. $\square$

3.3   Testing NFA equivalence

It is possible to extend Algorithm 2 to test the equivalence of NFAs. The basic idea is to embed the powerset construction into the algorithm, although this must be done with some caution. Because of space limitations, we will only sketch this extension. We call this algorithm **HKe**.

Let $N_1 = (Q_1, \Sigma, \delta_1, I_1, F_1)$ and $N_2 = (Q_2, \Sigma, \delta_2, I_2, F_2)$ be two NFAs. We assume that Q_1 and Q_2 disjoint, and, we make $Q_N = Q_1 \cup Q_2$, $F_N = F_1 \cup F_2$, and $\delta_N(p,a) = \delta_i(p,a)$ for $p \in Q_i$. Consider Algorithm 2 with the following data: $q_0 = I_1$, $p_0 = I_2$, and for $p \in 2^{Q_N}$, $\delta(p,a) = \bigcup_{q \in p} \delta_N(q,a)$ and $\varepsilon(p) = 1$ if and only if $\exists q \in p : \varepsilon(q) = 1$. Notice that when dealing with NFAs it is essential to use the idea described in Subsection 3.2 and to adjust the FIND operation so that FIND(i) creates the set S_i if it does not exist. This way we avoid calling MAKE for each of the $2^{|Q_N|}$ sets, which would lead directly to the worst-case of the powerset construction.

Theorem 3. *Algorithm 2 can be applied to NFAs by embedding the powerset construction method.*

As any DFA is a particular case of an NFA, all the experimental results presented on Section 5 use Algorithm **HKe**, whether the finite automata being tested are deterministic or not.

4 Relationship with Antimirov and Mosses' method

4.1 Antimirov and Mosses' algorithm

The *derivative* [8] of a r. e. α with respect to a *symbol* $a \in \Sigma$, denoted $a^{-1}(\alpha)$, is defined recursively on the structure of α as follows:

$$a^{-1}(\emptyset) = \emptyset; \qquad\qquad a^{-1}(\alpha + \beta) = a^{-1}(\alpha) + a^{-1}(\beta);$$
$$a^{-1}(\epsilon) = \emptyset; \qquad\qquad a^{-1}(\alpha\beta) = a^{-1}(\alpha)\beta + \varepsilon(\alpha)a^{-1}(\beta);$$
$$a^{-1}(b) = \begin{cases} \epsilon, & \text{if } b = a; \\ \emptyset, & \text{otherwise}; \end{cases} \qquad a^{-1}(\alpha^*) = a^{-1}(\alpha)\alpha^*.$$

This notion can be trivially extended to words, and considering r. e. modulo the ACI axioms, Brzozowski [8] proved that, the set of derivatives of a r. e. α, $\mathcal{D}(\alpha)$, is finite. This result leads to the definition of *Brzozowski's automaton* which is equivalent to a given r. e. α: $D_\alpha = (\mathcal{D}(\alpha), \Sigma, \delta_\alpha, \alpha, F_\alpha)$ where $F_\alpha = \{d \in \mathcal{D}(\alpha) \mid \varepsilon(d) = \epsilon\}$, and $\delta_\alpha(d, a) = a^{-1}(d)$, for all $d \in \mathcal{D}(\alpha)$, $a \in \Sigma$.

Antimirov and Mosses [6] proposed a rewrite system for deciding the equivalence of two extended r. e. (with intersection), based on a complete axiomatization. This is a refutation method such that testing the equivalence of two r. e. corresponds to an iterated process of testing the equivalence of their derivatives. In the process, a Brzozowski's automaton is computed for each r. e. Not considering extended r. e., Algorithm 3 is a version of **AM**'s method, which was, essentially, the one proposed by Almeida *et al.* [3].

```
1   def AM(α,β):
2       S = {(α,β)}
3       H = ∅
4       while (α,β) = POP(S):
5           if ε(α) ≠ ε(β): return False
6           PUSH(H, (α,β))
7           for a ∈ Σ:
8               α' = a⁻¹(α)
9               β' = a⁻¹(β)
10              if (α',β') ∉ H: PUSH(S,(α',β'))
11      return True
```

Algorithm 3: A simplified version of algorithm **AM**.

4.2 A naïve HK algorithm

We now present a naïve version of the Algorithm 1. It will be useful to prove its correctness and to establish a relationship to the Antimirov and Mosses' method (**AM**). Let $A = (Q_1, \Sigma, p_0, \delta_1, F_1)$ and $B = (Q_2, \Sigma, q_0, \delta_2, F_2)$ be two DFAs, with $|Q_1| = n$ and $|Q_2| = m$, and Q_1 and Q_2 disjoint. Consider

Algorithm 4. Termination is guaranteed because the number of pairs of states pushed into S is at most mn and in each iteration one pair is popped from S. To prove the correctness we show that in H we collect the pairs of states of the relation R, defined below.

```
1   def HKn(A,B):
2       S = {(p_0,q_0)}
3       H = ∅
4       while (p,q) = POP(S):
5           PUSH(H,(p,q))
6           for a ∈ Σ:
7               p' = δ_1(p,a)
8               q' = δ_2(q,a)
9               if (p',q') ∉ H: PUSH(S,(p',q'))
10      for (p,q) in H:
11          if ε(p) ≠ ε(q): return False
12      return True
```

Algorithm 4: The algorithm **HKn**, a naïve version of **HK**.

Lemma 4. *In Algorithm 4, for all $(p,q) \in Q_1 \times Q_2$, $(p,q) \in S$ in a step $k > 0$ if and only if $(p,q) \in H$ for some step $k' > k$.*

Definition 5. Let R be defined as follows:

$$R = \{(p,q) \in Q_1 \times Q_2 \mid \exists x \in \Sigma^* : \delta_1(p_0,x) = p \wedge \delta_2(q_0,x) = q\}.$$

Lemma 6. *For all $(p,q) \in Q_1 \times Q_2$, $(p,q) \in S$ at some step of Algorithm 4, if and only if $(p,q) \in R$.*

Lemma 7. *In line 10, for all $(p,q) \in Q_1 \times Q_2$, $(p,q) \in R$ if and only if $(p,q) \in H$.*

Considering Lemma 6 and Lemma 7, the following theorem ensures the correctness of Algorithm 4.

Theorem 8. *$A \sim B$ if and only if for all $(p,q) \in R$, $\varepsilon(p) = \varepsilon(q)$.*
Proof: Suppose, by absurd, that A and B are not equivalent and that the condition holds. Then, there exists $w \in \Sigma^*$ such that $\varepsilon(\delta(p_0,w)) \neq \varepsilon(\delta(q_0,w))$. But in that case there is a contradiction because $(\delta(p_0,w),\delta(q_0,w)) \in R$. On the other hand, if there exists a $(p,q) \in R$ such that $\varepsilon(p) \neq \varepsilon(q)$, obviously A and B are not equivalent. □

The relation R can be seen as a relation on $(Q_1 \cup Q_2)^2$ which is reflexive and symmetric. Its transitive closure R^* is an equivalence relation.

Lemma 9. *$\forall (p,q) \in R$, $\varepsilon(p) = \varepsilon(q)$ if and only if $\forall (p,q) \in R^*$, $\varepsilon(p) = \varepsilon(q)$.*

Corollary 10. *$A \sim B$ if and only if $\forall (p,q) \in R^*$, $\varepsilon(p) = \varepsilon(q)$.*

The Algorithm **HK** computes R^* by starting with the finest partition in $Q_1 \cup Q_2$ (the identity). And if $A \sim B$, R^* is a right-invariance.

Corollary 11. *Algorithm 4 and Algorithm 1 are equivalent.*

4.3 Equivalence of the two methods

The Algorithm 4 can be modified to a *earlier refutation* version, as in Algorithm 2. In order to do so, we remove lines 10–11, and we insert a line equal to line 7 of Algorithm 2, before line 4. It is then obvious that Algorithm 3 corresponds to Algorithm 4 applied to Brzozowski's automata of two r. e., where these DFAs are incrementally constructed during the algorithm's execution. In particular, the halting conditions are the same considering the definition of final states in a Brzozowski's automaton.

Theorem 12. *Algorithm 3 (**AM**) corresponds to Algorithm 4 (**HKn**) applied to Brzozowski's automata of two regular expressions.*

4.4 Improving Algorithm AM with Union-Find

Considering the Theorem 12 and the Corollary 11, we can improve the Algorithm 3 (**AM**) for testing the equivalence of two r. e. α and β, by considering Algorithm 1 applied to the Brzozowski's automata correspondent to the two r. e. Instead of using a stack (H) in order to keep an history of the pairs of regular expressions which have already been tested, we can build the correspondent equivalence relation R^* (as defined for Lemma 9). Two main changes must be considered:

- One must ensure that the sets of derivatives of each regular expression are disjoint. For that we consider their disjoint sum, where derivatives w. r. t. a word u are represented by tuples $(u^{-1}(\alpha), 1)$ and $(u^{-1}(\beta), 2)$, respectively.

- In the UNION-FIND method, the FIND operation needs an equality test on the elements of the set. Testing the equality of two r. e.— even syntactic equality — is already a computationally expensive operation, and tuple comparison will be even slower. On the other hand, integer comparison, can be considered to be $O(1)$. As we know that each element of the set is unique, we may consider some hash function which assures that the probability of collision for these elements is extremely low. This allows us to safely use the hash values as the elements of the set, and thus, arguments to the FIND operation, instead of the r. e. themselves. This is also a natural procedure in the implementations of conversions from r. e. to automata.

We call **equivUF** to the resulting algorithm. The experimental results are presented on Table 3, Section 5.

4.5 Worst-case complexity analysis

In Almeida *et al.* [3] the algorithm **AM** was improved by considering partial derivatives [5]. The resulting algorithm (**equivP**) can be seen as the algorithm **HKe** applied to the partial derivatives NFA of a r. e. We present a lower bound for the worst-case complexity of this algorithm by exhibiting a family of r. e. for which the comparison method can be exponential on the number of alphabetical symbols $|\alpha|_\Sigma$ of a r. e. α. We will proceed by showing that the partial derivatives NFA N of a r. e. α is such that $|N| \in O(|\alpha|_\Sigma)$ and the number of states of the smallest equivalent DFA is exponential on $|N|$.

Figure 1 presents a classical example of a bad behaved case of the powerset construction, by Hopcroft *et al.* [11]. Although this example does not reach the 2^n states bound, the smallest equivalent DFA has exactly 2^{n-1} states.

Consider the r. e. family $\alpha_\ell = (a+b)^* a(a+b)^\ell$, where $|\alpha_\ell|_\Sigma = 3 + 2\ell = m$. It is easy to see that the NFA in Figure 1 is obtained directly from the application of the **AM** method to α_ℓ, with the corresponding partial derivatives presented on Figure 2.
Figure 1: NFA which has no equivalent DFA with less than 2^n states.
Figure 2: NFA obtained from the r. e. α using the **AM** method.

The set of the partial derivatives

$$PD(\alpha_\ell) = \{\alpha_\ell, (a+b)^\ell, \ldots, (a+b), \epsilon\}$$

has $\ell + 2 = \frac{m+1}{2}$ elements, which corresponds to the size of the obtained NFA. The equivalent minimal DFA has $2^{\ell+1} = 2^{\frac{m-1}{2}}$ states.

5   Experimental results

In this section we present some experimental results of the previously discussed algorithms applied to DFAs, NFAs, and r. e. We also include the same results of the tests using Hopcroft's (**Hop**) and Brzozowski's (**Brz**) [7] automata minimization algorithms. The random DFAs were generated using publicly available tools[1][2]. The NFAs dataset was obtained with a set of tools described by Almeida *et al.* [4]. All the algorithms were implemented in the Python programming language. The tests were executed in the same computer, an Intel® Xeon® 5140 at 2.33GHz with 4GB of RAM. Table 1 shows the

Table 1: Running times for tests with complete accessible DFAs.

results of experimental tests with 10.000 pairs of complete ICDFAs. Due to space constraints, we only present the results for automata with $n \in \{5, 50\}$ states over an alphabet of $k \in \{2, 50\}$ symbols. Clearly, the methods which do not rely in minimisation processes are *a lot* faster. Below (Eff.) appears the *effective* time spent by the algorithm itself while below (Total) we show the *total* time spent, including overheads, such as making a DFA complete, initializing auxiliary data structures, etc. All times are expressed in seconds, and the algorithms that were not finished after 10 hours are accordingly signaled.

---

The algorithm **Brz** is by far the slowest. The algorithm **Hop**, although faster, is still several orders of magnitude slower than any of the algorithms of the previous sections. We also present the average number of iterations (Iter.) used by each of the versions of algorithm **HK**, per pair of automata. Clearly, the refutation process is an advantage. **HKn** running times show that a linear set merging algorithm (such as UNION-FIND) is by far a better choice than a simple history (set) with pairs of states. **HKs** is a version of **HKe** which uses the automata string representation proposed by Almeida *et al.* [2, 14]. The simplicity of the representation seemed to be quite suitable for this algorithm, and actually cut down both running times to roughly half. This is an example of the impact that a good data structure may have on the overall performance of this algorithm.

Table 2: Running times for tests with 10.000 random NFAs.

		$n = 5$						$n = 50$				
		$k = 2$			$k = 20$			$k = 2$			$k = 20$

Table 2 shows the results of applying the same set of algorithms to NFAs. The testing conditions and notation are as before, adding only the *transition density* d as a new variable, which we define as the ratio of the number of transitions over the total number of possible transitions (kn^2). Although it is clear that **HKe** is faster, by at least one order of magnitude, than any of the other algorithms, the peculiar behaviour of this algorithm with different transition densities is not easy to explain. Considering the simplest example of 5 states and 2 symbols, the dataset with a transition density $d = 0.5$ took roughly twice as long as those with $d \in \{0.1, 0.8\}$. On the other extreme, making $n = 50$ and $k = 2$, the hardest instance was $d = 0.1$, with the cases where $d \in \{0.5, 0.8\}$ present similar running times almost five times faster. In our largest test, with $n = 50$ and $k = 20$, neither **Hop** nor **Brz** finished within the imposed time limit. Again, $d = 0.1$ was the hardest instance for **HKe**, which also did not finish within the time limit, although the cases where $d \in \{0.5, 0.8\}$ present similar running times.

Table 3 presents the running times of the application of **HKe** to r. e. and their comparison with the algorithms presented by Almeida *et al.* [3], where **equiv** and **equivP** are the functional variants of the original **AM** algorithm. **equivUF** is the UNION-FIND improved version of **equivP**. Although the results indicate that **HKe** is not as fast as the direct comparison methods presented in the cited paper, it is clearly faster than any minimisation process. The improvements of **equivUF** over **equivP** are not significant (it is actually considerably slower for r. e. of length 100 with 2 symbols). We suspect that this is related to some optimizations applied by the Python interpreter. We state this based on the fact that when both algorithms are executed using a profiler, **equivUF** is almost twice faster than **equivP** on most tests.

We have no reason to believe that similar tests with different implementations of these algorithms

Table 3: Running times (seconds) for tests with 10.000 random r. e.

	Size/Alg.	Hop	Brz	AM	Equiv	EquivP	HKe	EquivUF
$k = 2$	10	21.025	19.06	26.27	7.78	5.512	7.27	5.10
	50	319.56	217.54	297.23	36.13	28.05	64.12	28.69
	75	1043.13	600.14	434.89	35.79	23.46	139.12	60.09
	100	7019.61	1729.05	970.36	60.76	48.29	183.55	124.00
$k = 5$	10	42.06	25.99	32.73	9.96	7.25	8.69	6.48
	50	518.16	156.28	205.41	33.75	26.84	67.7	21.53
	75	943.65	267.12	292.78	35.09	25.17	161.84	28.61
	100	1974.01	386.72	567.39	54.79	45.41	196.13	37.02
$k = 10$	10	61.60	31.04	38.27	10.87	8.39	9.26	7.47
	50	1138.28	198.97	184.93	34.93	28.95	72.95	22.60
	75	2012.43	320.37	271.14	35.77	26.92	195.88	30.61
	100	4689.38	460.84	424.67	52.97	44.58	194.01	39.23

would produce significantly different ordering of its running times from the one here presented. However, it is important to keep in mind, that these are experimental tests that greatly depend on the hardware, data structures, and several implementation details (some of which, such as compiler optimizations, we do not utterly control).

6   Conclusions

As minimality or equivalence for (finite) transition systems is in general intractable, right-invariant relations (bisimulations) have been extensively studied for nondeterministic variants of these systems. When considering deterministic systems, however, those relations provide non-trivial improvements. We presented several variants of a method by Hopcroft and Karp for the comparison of DFAs which does not use automata minimization. By placing a refutation condition earlier in the algorithm we may achieve better running times in the average case. This is sustained by the experimental results presented in the paper. We extended this algorithm to handle NFAs. Using Brzozowski's automata, we showed that a modified version of Antimirov and Mosses' method translates directly to Hopcroft and Karp's algorithm.
